1 Introduction

Exploring the dataset “Terror Attacks” led to formulating the following question: is it possible to predict the location of a terrorist attack given a list of features of this attack?

The goal of this project is to answer this question using data analysis tools provided by the course “A Network Tour Of Data Science”.

2 Exploring the Data

2.1 Relationships Dataset

Figure 1: *Terrorist relation dataset graph, colouring the relation type*

The nodes of the network are relations between terrorists. These nodes are connected together if the relations share one individual.

2.2 Terror Attacks Dataset

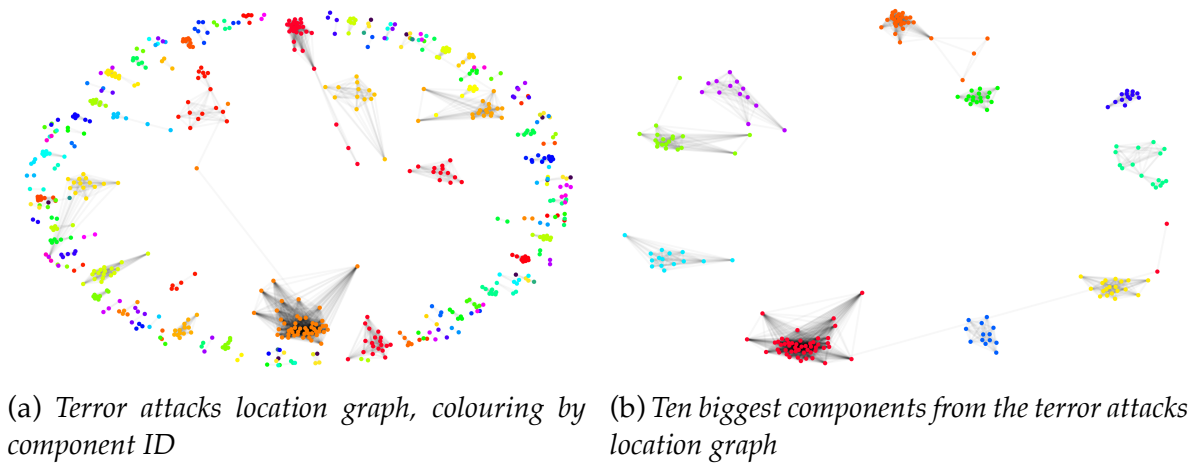

Figure 2: *Graphs from the terror attacks dataset*

3 Data Quality

3.1 Terrorist Relations Dataset

3.2 Terror Attacks Dataset

Multiple issues regarding data quality have been found in this dataset:

Breadness The dataset comprises attacks ranging from 1969 to 1950 and spanning the entire globe. Simple and relevant explanations for the graph formation or properties are not likely to be found, since the mechanisms behind two different attacks can be entirely different.

Structure Half of the nodes are isolated, hence the topological information they carry in the graph is very limited. What is more, because of the transitivity relation described in Section 2.2, connected components are in most of the cases complete, hence isotropic.

Reliability Errors have been found in the data. For example nodes `Djibouti_Youth_Movement_19900927` and `Armed_Islamic_Group_19950711` have been connected, whereas the first attack took place in Djibouti [1] and the second one in Paris [2]. Hence algorithms using the data must tolerate some error in order to avoid overfitting.

Incompleteness [3]

4 Predictions

The algorithm used to predict the terror attack location is the following:

1. From the dataset, select the 10 biggest connected components (“component” in what follows).

2. Sort the dataset by date of terror attack.
3. At this point, a component represents a location, and the nodes are the terror attacks in chronological order.
4. Select one node per component that is strongly connected to the others, the “lead” node.
5. Find the lead node l^* that is the most strongly linked to the new node (i.e. the next terror attack).
6. The predicted location of the next terror attack is the location of the component l^* belongs to.

The determination of the lead node uses the features vector supplied with each node, and a weighting function w . Let w be the application that returns a weight for each pair of nodes (n_1, n_2) in the graph \mathcal{G} , defined as

$$w : \mathcal{G}^2 \rightarrow \mathbb{R}^+ \quad (1)$$

$$(n_1, n_2) \mapsto f(|n_1 - n_2|) \quad (2)$$

where

$$|n_1 - n_2| = \|\text{features}(n_1) - \text{features}(n_2)\|_2 \quad (3)$$

$\text{features}(n)$ is a binary features vector for each node n in \mathcal{G} and $f : \mathbb{R}^+ \mapsto \mathbb{R}^+$ is the node distance weighting. Examples for f are given in Table 1.

For each connected component, the lead node is determined as described below.

Algorithm 1: Finding the lead node of a connected component with weighted edges

Data: Connected component C

Result: Lead node n_l

Initialise $s(n)$ to zero. s is a dictionary mapping a score $s(n)$ for each node n

for each edge e from C do

Let $e = (n_1, n_2)$, w be the weight of e
 $s(n_1) \leftarrow s(n_1) + w$
 $s(n_2) \leftarrow s(n_2) + w$

end

return $n_l = \arg \max_{n \in C} s(n)$

Finally, the prediction algorithm is presented below.

Algorithm 2: Finding the predicted location of the next terror attack

Data: Set of connected components $\{C_i^t\}, i = 1, \dots, 10$, and the features vector of the next terror attack n_{t+1} , i.e. $\text{feature}(n_{t+1})$, at each timestep t

Result: Location prediction p_t for time $t + 1$ at time t , at each timestep t

for each timestep t do

Compute the lead component $l(C_i^t)$ for each component C_i^t
 $p_t = \arg \max_{i=1, \dots, 10} w(n_{t+1}, l(C_i^t))$

end

4.1 Justification

- topology
- formation, not labelling
- robustness
- lead choice justify mesh

4.2 Results

Table 1: *Prediction accuracy for different node distance weightings f*

Weighting		Best skewness ζ	Accuracy
Gaussian:	$f(d) = e^{-d^2/\zeta} - e^{-1/\zeta}$	0.01	50.5 %
Log-Exponential:	$f(d) = e^{-d} \log\left(\frac{1+\zeta}{d+\zeta}\right)$	0.1	50 %
Linear:	$f(d) = 1 - d$	N.A.	47 %
Square:	$f(d) = \begin{cases} 1 & d < \zeta \\ 0 & \text{otherwise} \end{cases}$	0.1	43 %

5 Conclusion

Section 3.2 explains that the “Terror Attacks” dataset contains flaws that make it difficult to analyze.

However, the results in Table 1 show that predicting the location of an attack with its features is feasible even though the prediction is not very efficient. This result suggests that there is a link between the location of an attack and its characteristics (such as the type of the attack).
